Background: Idiopathic pulmonary fibrosis (IPF) is a chronic progressive interstitial lung disease with severe pulmonary fibrosis. The main cause of IPF-associated death is acute exacerbation of IPF (AE-IPF). This study aims to develop a rat model of AE-IPF by two intratracheal perfusions with bleomycin (BLM).

Methods: Ninety male Sprague Dawley (SD) rats were randomized into three groups: an AE-IPF model group (BLM + BLM group), an IPF model group (BLM group), and a normal control group. Rats in the BLM + BLM group underwent a second perfusion with BLM on day 28 after the first perfusion with BLM. Rats in the other two groups received saline as the second perfusion. Six rats in each group were sacrificed on day 31, day 35, and day 42 after the first perfusion, respectively. Additional 18 rats in each group were observed for survival.

Results: Rats in the BLM + BLM group had significantly worse pulmonary alveolar inflammation and fibrosis than rats in the BLM group. Rats in the BLM + BLM group also developed large amounts of hyaline membrane, showed high levels of albumin (ALB) and various inflammatory factors in the bronchoalveolar lavage fluid (BALF), and had markedly increased lung water content. Furthermore, rat survival was reduced in the BLM + BLM group. The pathophysiological characteristics of rats in the BLM + BLM group resemble those of patients with AE-IPF.

Conclusions: A second perfusion with BLM appears to induce acute exacerbation of pulmonary fibrosis and may be used to model AE-IPF in rats.

Keywords: Idiopathic pulmonary fibrosis (IPF); acute exacerbation; model; bleomycin (BLM)

Introduction

Idiopathic pulmonary fibrosis (IPF) is a chronic progressive interstitial lung disease with severe pulmonary fibrosis. The etiology of IPF remains unclear. Patients usually only survive 2–3 years after being diagnosed with IPF (1,2). The incidence and development of IPF are associated with epithelial cell injury, fibrocyte proliferation, inflammatory reactions, and extracellular matrix deposition (3,4). The pathological manifestation of IPF is usual interstitial pneumonia (UIP) (3,5). Currently, the mortality in patients with IPF is quite high. However, effective treatments for IPF are lacking (6). The main cause of IPF-associated death is acute exacerbation of IPF (AE-IPF), which accounts for
more than 50% of IPF-related deaths (7). Kondoh et al. firstly described AE-IPF (8) and found that AE-IPF also presented diffuse alveolar damage (DAD) in addition to UIP (7). Most patients with AE-IPF are unable to tolerate bronchoscopy or lung biopsy because of their critical condition. Lack of the biopsy of AE-IPF substantially limits in-depth investigations of AE-IPF. Experimental animal models that could mimic AE-IPF would be useful tools to study AE-IPF.

Animal models of bleomycin (BLM)-induced IPF were initially described in 1970 (9). The rat model of IPF, which is developed by an intratracheal perfusion with BLM, has already been commonly used (10-12). Theoretically, a second intratracheal perfusion with BLM should induce additional lung injury in the rats that already develop pulmonary fibrosis from the first perfusion. The additional lung injury may resemble the pathological characteristics of AE-IPF. This study aims to test this approach to develop a rat model of AE-IPF. The pathological characteristics of the rat model were also investigated.

Methods

Chemicals and reagents

BLM was purchased from the Nippon Kayaku Co. Ltd. (Tokyo, Japan). Isoflurane and pentobarbital sodium were purchased from Yuyan Instruments Co., Ltd. (Shanghai, China). Neutral formalin (10%) was purchased from Wuhan Goodbio technology Co., Ltd. (Wuhan, China). Rat IL-6, IL-10, IL-17A and TGF-β enzyme-linked immunosorbent assay (ELISA) kits were purchased from Neo Bioscience Technology Co. (Shenzhen, China). Tissue RNA kit was purchased from Biomiga Inc. (San Diego, USA). The primer sequences were designed and synthesized by Sangon Biotech Co., Ltd. (Shanghai, China). The real-time PCR (RT-PCR) kit was purchased from TOYOBO Life Science (Osaka, Japan).

Animals

The protocol for animal maintenance and experiments was approved by the Institutional Animal Care and Use Committee at Tongji University. A total of 90 male Sprague Dawley (SD) rats (SPF grade, body weight: 100±10 g) were purchased from Shanghai SLAC Laboratory Animal Co., Ltd., China. The rats were maintained at 24±1 ℃ and a relative humidity of 40–80% according to the Guidelines for Animal Experimentation of Tongji University (Shanghai, China). The rats had free access to food and water and were housed for 1 week to adapt the new environment before being used for experiments.

Development of animal models

The rats were randomized into the following three groups: a BLM + BLM group (n=40), a BLM group (n=25), and a control group (n=25). BLM was dissolved in saline to a final concentration of 2.5×10⁻³ mg/L. All the rats were anesthetized by isoflurane inhalation and then intratracheally perfused with BLM (5 mg/kg) (for the BLM + BLM and BLM groups) or the same volume of saline (control group) by laryngoscopy (Penn-Century, Inc., LS-2-R, USA). The second perfusion was performed on day 28 after the first perfusion. Based on our preliminary experiments (see supplementary appendix, Figure S1), 7 mg/kg BLM was the optimal dose for the second perfusion in the BLM + BLM group. The same volume of saline was perfused in the other two groups (the BLM and control groups). Six rats were selected randomly from each group on day 31, day 35, and day 42 after the first perfusion, respectively, and then anesthetized by an intraperitoneal injection of 2% pentobarbital sodium. Subsequently, blood was collected from the abdominal aorta to analyze blood gas. After the rats were sacrificed by exsanguination, supernatant of the bronchoalveolar lavage fluid (BALF) from the right lung was preserved at −80 ℃; the lung tissues were dissected. The left lung was preserved in liquid nitrogen for RT-PCR analysis. The anterior and middle lobe of the right lung was fixed in 10% neutral formalin for hematoxylin and eosin (H & E) staining and Masson staining, and the posterior lobe of the right lung was used to analyze lung water content (Figure 1).

Histopathology of lung tissues

The anterior and middle lobe of the right lung was fixed in 10% neutral formalin for 48 hours, embedded in paraffin, and then sectioned for H & E staining and Masson staining. The stained lung tissue sections were analyzed on a pathological section scanner (4× magnification, Leica Biosystems, SCN400, Germany). All H & E-stained sections were analyzed and scored for acute lung injury (ALI) severity by two experienced pathologists, who were blinded for the group allocation (13). The average scores were used. ALI severity was scored based on the severity
of the following four histopathological features: (I) alveolar congestion; (II) bleeding; (III) inflammatory cell infiltration; and (IV) alveolar wall thickening or a hyaline membrane formation. The severity of each feature was scored from 0–4 with 0 representing the least and 4 representing the most severe, and the total scores of the four features was used for statistical analysis. All Masson-stained sections were analyzed. Three observation fields were randomly selected from each Masson-stained section, and the percentage of blue areas, which represent collagen deposition, over the total tissue area (i.e., percentage area of collagen deposition) was calculated for each image using Image-Pro Plus 6.0 software.

**Arterial blood gas analysis**

Rats were anesthetized by an intraperitoneal injection of 2% pentobarbital sodium (2 mL/kg), and 1.5 mL blood from the abdominal aorta was then collected for immediate arterial blood gas analysis (Radiometer Medical ApS., ABL800, Denmark).

**Lung water content**

Lung water content was measure to estimate lung edema. A total of 250 mg lung lobe was collected from the same position of the lung from each rat and dried overnight in a freeze-dryer (Beijing Sihuan Company, LGJ-10D, China). The difference between dry weight and wet weight of each sample was calculated as lung water content (lung water content = wet weight – dry weight).

**Measurement of inflammatory factors and albumin (ALB) in the BALF supernatant**

The BALF was centrifuged (4 °C, 3,000 rpm, 5 minutes), and the supernatants were collected. The levels of inflammatory factors (IL-6, IL-10, IL-17A, and TGF-β) were analyzed using ELISA kits according to the manufacturer's instruction. The absorbance at 450 nm was determined in a plate reader (Thermo Fisher Scientific Inc., Varioskan Flash, USA). ALB levels in the supernatant of BALF were measured using the bromocresol green combination method by the Laboratory Department of Shanghai Pulmonary Hospital.

**Determination of NF-κB mRNA expression in lung tissues by RT-PCR**

Total RNA was extracted from the lung tissues following the instruction from the kit (Biomiga, USA). cDNA was synthesized under the following condition: 65 °C for 5 minutes (heat denaturation) followed by immediate preservation on ice, 37 °C for 15 minutes, and 98 °C for 5 minutes. PCR was then performed according to the following condition: pre-denaturation at 95 °C for 1 minute, 40 cycles of denaturation at 95 °C for 15 seconds, annealing at 55 °C for 15 seconds, and extension at 60 °C for 40 seconds using a kit from TOYOBO Life Science. The linear correlation between the copy number of mRNA and cycle threshold (CT) was analyzed using Applied Biosystems® 7500 Fast Real-Time PCR Systems, and the standard curve was then prepared. Relative expression level of NF-κB mRNA was calculated according to the equation: $2^{-\Delta\Delta CT} \times 100\%$, $\Delta CT = CT$ of the target gene $-$ $CT$ of the internal reference ($\beta$-Actin). The primer sequences are described in Table 1.

**Survival analysis and body weight measurement**

Additional 18 rats in each group (n=18) were observed for survival analysis. Rat survival was monitor daily for 8 weeks after the first perfusion. Rat body weight was measured weekly.
Statistical analyses

The statistical analysis software Graphpad prism 5 (La Jolla, CA, USA) was used. Continuous variables are presented as mean ± standard deviation (SD). Inter-group comparisons were performed using the independent sample t-test and one-way AVOVA analysis of variance followed by Newman-Keuls multiple comparison test. Repeated measurement data were analyzed. Survival curve was plotted using the Kaplan-Meier method, and the survival time was compared by the log-rank test. P<0.05 represents statistical significance.

Results

Rats in the BLM + BLM group had worse pulmonary inflammation and fibrosis

H & E staining showed severe ALI in the BLM + BLM group. Normal alveolar structures disappeared; alveolar septa became markedly thickened; congestion and edema were developed; large amounts of inflammatory cells infiltrated into the interstitium and alveoli (Figure 2A). In addition, hyaline membranes were formed obviously on day 31 (Figure 2B). ALI score was significantly higher in the BLM + BLM group than in the BLM group (day 31: P=0.0005; day 35: P=0.0219; day 42: P=0.0118; Figure 2C). In the BLM + BLM group, the ALI score on day 31 was significantly higher than that on day 35 and day 42 (day 35: P=0.0002; day 42: P=0.0001; Figure 2C). Masson-staining showed large amounts of collagen deposition and apparent pulmonary fibrosis in the BLM + BLM and BLM groups (Figure 2D). Quantification of the Masson staining demonstrated significantly greater collagen deposition in the BLM + BLM and BLM groups than in the control group at all of the three time points (All P<0.05, Figure 2E). The collagen deposition was not statistically significantly different between the BLM + BLM group and the BLM group on day 31 and day 35, but was significantly higher in the BLM + BLM group than in the BLM group on day 42 (P=0.0007, Figure 2E).

Arterial blood gas analysis

On day 3 and day 7 after the second perfusion (i.e., day 31 and day 35 after the first perfusion), the partial pressure of arterial oxygen (PaO₂) was significantly lower in the BLM + BLM group than in the other two groups (day 31: BLM + BLM group vs. BLM group, P=0.0148, BLM + BLM group vs. control group, P=0.0050; day 35: BLM + BLM group vs. BLM group, P=0.0002, BLM + BLM group vs. control group, P=0.0024, Figure 3).

Lung water content

On day 3 and day 7 after the second perfusion (i.e., day 31 and day 35 after the first perfusion), the lung water content was significantly higher in the BLM + BLM group than in the other two groups (day 31: BLM + BLM group vs. BLM group, P=0.0101, BLM + BLM group vs. control group, P=0.0049; day 35: BLM + BLM group vs. BLM group, P=0.0168, BLM + BLM group vs. control group, P=0.0022, Figure 4).

Survival analysis

Rats in the BLM + BLM group were markedly less active and suffered respiratory embarrassment after the second BLM perfusion, and some rats developed thoracic deformity. On day 1 after the first perfusion, two rats in the BLM + BLM group and one in the BLM group died, and the control group had no death. On day 56, the mortality rate in the BLM + BLM group (56.25%, 9/16) was markedly higher than that in the BLM group (11.76%, 2/17, P=0.0222, Figure 5). One week after the first perfusion, rats receiving BLM perfusion had significantly lower body weight than rats in the control group (Figure 6). On day 56 (week 8), rats in the BLM + BLM group had significantly lower mean body weight (225.6±19.96 g) than rats in the BLM group (418.4±12.62 g, P<0.0001, Figure 6).

Figure 2  Histopathology of the lung tissues (n=6 for each group). (A) Representative images of H & E staining of lung tissues (20×, LEICA SCN400, scale bars represent 500 μm). The BLM + BLM group shows thickened alveolar septa, pulmonary congestion and edema, infiltration of inflammatory cells into the interstitium and alveoli, and large amounts of exudates and bleeding foci in the alveoli. The BLM group presents milder inflammation and fibrosis compared with the BLM + BLM group. The control group shows a normal lung structure; (B) an image of H & E staining (100×, LEICA SCN400, scale bars represent 100 μm) from the BLM + BLM group on day 31. The arrow is pointing to the hyaline membrane; (C) * represents significantly different between the BLM + BLM group and the BLM group, day 31: P=0.0005, day 35: P=0.0219, day 42: P=0.0118. # represents significantly different in BLM + BLM group between day 31 vs. day 35 and day 42, day 35: P=0.0002, day 42: P=0.0001; (D) representative images of Masson staining of lung tissues (400×). Both the BLM + BLM and BLM groups show high collagen deposition at all of the three time points, and the alveolar structure was severely damaged. The control group presents mild collagen deposition in the alveolar septa on day 42; (E) quantification of collagen deposition. * represents that collagen deposition was significantly higher in the BLM + BLM group than in the BLM group on day 42, P=0.0007; * represent that collagen deposition was significantly higher in the BLM + BLM and BLM groups than in the control group, P<0.05. BLM, bleomycin; H & E, hematoxylin and eosin.
Figure 3 Arterial blood gas. On day 31, PaO$_2$ was significantly lower in the BLM + BLM group than in the other two groups, and PaO$_2$ was also significantly lower in the BLM group than in the control group. On day 35, PaO$_2$ in the BLM + BLM group was significantly lower than in the other two groups. On day 42, all three groups show similar PaO$_2$. PaO$_2$, partial pressure of arterial oxygen; BLM, bleomycin.

Figure 4 Lung water content. On day 31 and day 35, lung water content was significantly higher in the BLM + BLM group than in the BLM group. BLM, bleomycin.

Figure 5 Survival curves. Additional 18 rats in each group were observed for survival. The mortality rate on day 56 was 56.25% (9/16), 11.76% (2/17), and 0% (0/18) for the BLM + BLM group, BLM group, and control group, respectively. Rat survival was significantly lower in the BLM + BLM group than in BLM groups (P=0.0222). BLM, bleomycin.

Figure 6 Body weight. * represent that the body weight in the BLM + BLM group and BLM group was significantly lower than that in the control group, P<0.0001; # represent the body weight in the BLM + BLM group was significantly lower than that in the BLM group, P<0.0001. On day 56, the mean body weight in the BLM + BLM group was 225.6±19.96 g, while the mean body weight in the BLM group was 418.4±12.62 g. BLM, bleomycin.

Rats in the BLM + BLM group had elevated levels of inflammatory factors and ALB in the BALF

During the first week after the second perfusion, IL-6 and IL-10 levels in the BALF in the BLM + BLM group were significantly higher than those in the other two groups (All P<0.05, Figure 7A,B), indicating that the second perfusion with BLM may induce acute inflammation. On day 31, the ratio of IL-6 to IL-10 in the BLM + BLM group was 6.9778±0.7674, and then the ratio gradually decreased at later time (Figure 7C). On day 35 and day 42, IL-17A level was evidently higher in the BLM + BLM group than in the BLM group (day 35, P=0.0477; day 42, P=0.0306, Figure 7D), and TGF-β level was markedly higher in the BLM + BLM group than in the BLM group (day 35, P=0.0076; day 42, P=0.0021, Figure 7E). These data suggest an exacerbation of pulmonary fibrosis after the second perfusion with BLM. On day 31, the ALB level was significantly higher in the BLM + BLM group than in the BLM and control groups (BLM + BLM group vs. BLM group, P=0.0338; BLM + BLM group vs. control group, P=0.0167, Figure 7F). These results are consistent with the ALI histopathology.

Rats in the BLM + BLM group had significantly increased expression of NF-kB mRNA in the lung tissue

RT-PCR revealed that on day 31, day 35, and day 42 after the first perfusion, the relative NF-kB mRNA level was significantly higher in the BLM + BLM group than in the
Figure 7 The levels of inflammatory factors and ALB in the supernatant of BALF (n=6 for each group). (A) IL-6 level was significantly higher in the BLM + BLM group than in the BLM group on day 31 and day 35; (B) IL-10 level was significantly higher in the BLM + BLM group than in the BLM group on day 31 and day 35; (C) on day 31, the ratio of IL-6 to IL-10 in the BLM + BLM group reached a peak of 6.9778±0.7674. The ratio then gradually decreased at subsequent time points; (D) IL-17A level was significantly higher in the BLM + BLM group than in the BLM group on day 35 and day 42; (E) TGF-β level was significantly higher in the BLM + BLM group than in the BLM group on day 35 and day 42; (F) ALB level was significantly higher in the BLM + BLM group than in the other two groups on day 31. ALB, albumin; BALF, bronchoalveolar lavage fluid; BLM, bleomycin.

BLM group (day 31, P=0.0372; day 35, P=0.0493; day 42, P=0.0255; Figure 8). NF-κB plays an important role in inflammatory response. An increased NF-κB expression suggests an elevated inflammatory response.

Discussion

Environmental pollution, seasonal changes, and lung-injuring drugs can induce AE-IPF (7,14). Patients with AE-IPF are usually in critical condition. Unfortunately, effective treatments for AE-IPF are still unavailable (15,16). Animal models to properly mimic AE-IPF are useful tools to study AE-IPF pathogenesis and develop effective therapies. In the current study, we developed a rat model of AE-IPF by two intratracheal perfusions with BLM.

An intratracheal perfusion with BLM induces acute alveolar inflammation accompanied with an increased infiltration of leukocytes, such as macrophages, granulocytes, and lymphocytes. These inflammatory cells stimulate fibroblast proliferation and myofibroblast activation, ultimately leading to pulmonary fibrosis (17). Animal models of BLM-induced pulmonary fibrosis have been widely used to study IPF (10-12). Brown et al. have shown that repetitive intratracheal perfusion with BLM worsens the BLM-induced lung injury and fibrosis in rats (18). Based on their study, we developed a rat AE-IPF
model by a second intratracheal perfusion with BLM in rats that already had initial BLM-induced pulmonary fibrosis. We found that rats in the AE-IPF model group (BLM + BLM group) presented pulmonary fibrosis with apparent DAD and large amounts of hyaline membrane. In addition, rats receiving two perfusions with BLM had poor survival, elevated ALB levels in the BALF, increased lung water content, and high expression of various inflammatory factors. These findings suggest a successful development of a rat model of AE-IPF.

IL-6, a pro-inflammatory cytokine and an important biomarker for AE-IPF (19), is stimulated by NF-κB (20). IL-10, an anti-inflammatory cytokine, inhibits inflammation by suppressing NF-κB expression and activity (21). In the current study, IL-10 peaked (day 35) 4 days later than IL-6 (day 31) and the IL6/IL10 ratio reduced gradually in the BLM + BLM group, indicating that the second perfusion induces dynamic inflammatory changes in the lung. TGF-β has been found to be closely associated with pulmonary fibrosis (22). TGF-β and IL-6 can synergistically promote Th-17 T cell differentiation and stimulate IL-17A expression (23). IL-17A regulates neutrophil aggregation (24,25) and activates NF-κB to induce TNF-α production, thus causing inflammation and tissue injury (25,26). We found that on day 7 after the second perfusion with BLM, both TGF-β and IL-17A expression reached the maximum, suggesting a severe lung inflammation. The lung inflammation may eventually lead to chronic inflammation and fibrosis.

In the current study, the dynamic changes in the inflammatory factors, such as IL-6, IL-10, TGF-β, and IL-17A, indicate that the second perfusion may induce a rapid over-expression of pro-inflammatory factors, which counteract the anti-inflammatory factors. Thus, the net effects were acute inflammation and an exacerbation of the first perfusion-induced pulmonary fibrosis. These inflammatory events resemble the pathophysiological changes in patients developing AE-IPF.

Patients with AE-IPF often suffer severe infiltrative edema and alveolar collapse because of alveolar epithelial and endothelial cell damage, and consequently develop respiratory failure. PaO₂ reduction is one of the key criteria to diagnose AE-IPF (15,27). Rats in the BLM + BLM group presented a significant increase in lung water content and a sharp decrease in PaO₂ 1 week after the second perfusion. Furthermore, rats in the AE-IPF model group (BLM + BLM group) also had respiratory embarrassment and high mortality rate. These pathophysiologic features are similar to the clinical manifestation of patients with AE-IPF.

Our results showed that a second perfusion with BLM (7 mg/kg) induced apparent DAD in the rats that already developed pulmonary fibrosis induced by the first perfusion. The worst lung injury occurred on day 3 after the second perfusion, and the ALI gradually exacerbated the pulmonary fibrosis. The course of lung injury development in rats receiving two perfusions is very similar to that in patients with AE-IPF. The previous study has demonstrated a murine model of gammaherpesvirus-induced pulmonary fibrosis (28). However, the roles of infection in the development of AE-IPF in patients are still unclear. The rat model of AE-IPF in the current study is simpler and safer than the animal models of AE-IPF induced by infection, and shows satisfactory reproducibility. Previous studies that used repetitive intratracheal perfusion with BLM have shown that consecutive weekly intratracheal instillations of BLM result in severe pulmonary fibrosis (18,29). In the rat model of the current study, the ALI induced by the second perfusion was associated with lung fibrosis, and this fibrosis-related ALI mimics human AE-IPF. In our previous study, we have successfully established a mouse model of AE-IPF by twice BLM administrations (30). The current study has novelty although we have already published a mouse model of AE-IPF using two administrations of BLM. First, we tested dose response and time course in the rat model in the current study (supplementary appendix file, Figure S2). Second, compared to the mouse model, the rat model was established by intratracheal perfusion with BLM or saline under laryngoscopy, which substantially improves the efficiency of intratracheal perfusion with BLM and reduces the risk that the perfusion solution may mistakenly enter the esophagus. Third, PaO₂ reduction is one of the key criteria.
to diagnose AE-IPF. Thus, we added arterial blood gas analysis in the current study for a more accurate assessment of AE-IPF in the rat model. The last but not the least, most of the patients with AE-IPF are usually so critical ill that oral medication may fail to relieve their symptoms efficiently. Therefore, medications are usually administered via intravenous injection for those patients. It is critical to develop an experimental animal model of AE-IPF, which can be used to test drugs administered by intravenous injection. Compared with mice, rats have thicker caudal vein and thus intravenous injection is technically easier for rats than mice. Thus, this rat model of AE-IPF may be more useful to test new drugs than the mouse model.

Conclusions
The pathophysiological characteristics of rats receiving two perfusions with BLM resemble to those of patients with AE-IPF. Thus, a second perfusion with BLM appears to induce AE-IPF and may be used to model AE-IPF in rats.

Supplementary methods

Rats were randomized into three groups: a low-dose group (3 mg/kg, LD group, n=20), a moderate-dose group (5 mg/kg, MD group, n=20), and a high-dose group (7 mg/kg, HD group, n=20). Bleomycin (BLM) was dissolved in saline to reach the final concentration of 2.5 mg/mL. All of the rats were anesthetized by isoflurane inhalation and then intratracheally perfused with 5 mg/kg BLM by laryngoscopy. The second perfusion with BLM at 3, 5, or 7 mg/kg was performed on day 28 after the first perfusion. Three rats were selected randomly from the three dose groups on day 31, day 35, and day 42 after the first perfusion, respectively, and then anesthetized by an intraperitoneal injection of 2% pentobarbital sodium. The rats were subsequently sacrificed by exsanguination.

Supernatant of the bronchoalveolar lavage fluid (BALF) from the right lung was collected to analyze the level of inflammatory factors (IL-6, IL-10 and TGF-β) using an enzyme-linked immunosorbent assay (ELISA) kit according to the manufacturer’s instructions. The left lung lobe was fixed in 10% neutral formalin for 48 hours, embedded in paraffin, and sectioned for hematoxylin and eosin (H & E) staining. Histology sections were analyzed on a pathological section scanner. All H & E-stained sections were analyzed with LEICA SCN400 (20×, scale bars represent 500 μm) by two experienced pathologists, who were blinded for the group allocation.

Figure S1 Images of hematoxylin and eosin (H & E) staining of histopathological sections of lung tissues collected on day 31, day 35, and day 42 (20×, scale bars represent 500 μm). Rats received a second intratracheal perfused with BLM at 3, 5, or 7 mg/kg on day 28 after the first perfusion. All of the rats lost normal alveolar structure and showed markedly thickened alveolar septa. In particularly, rats receiving 7 mg/kg BLM as the second perfusion showed severe acute lung injury (ALI), pulmonary congestion and edema, infiltration of inflammatory cells into the interstitium and alveoli, and obvious hyaline membranes on day 31, which are the typical histopathological characteristics in patients with AE-IPF.
Figure S2 The levels of inflammatory factors in rats receiving different dose of BLM as the second perfusion. The levels of inflammatory factors (IL-6, IL-10, and TGF-β) were higher in the 7 mg/kg group than in the other two dose groups (5 and 3 mg/kg). Graphpad prism statistical software was used. The data are presented as mean ± standard deviation (SD).
