Background: In 2013, the Centers for Disease Control and Prevention (CDC) issued the concept of the ventilator-associated events (VAEs) as a quality indicator (QI) in the intensive care unit (ICU). A number of studies have been conducted in the United States and other Western countries to evaluate its practicality. However, information on VAEs in non-Western countries is scarce. The purpose of this preliminary study was to illuminate the incidence and associated mortality rate of VAEs in Japan, as a first step in the effort to determine its practicality.

Methods: We conducted a multi-center, retrospective review of patient medical record using VAEs surveillance algorithm. We analyzed 785 patients with ≥ 2 days of mechanical ventilator (MV), admitted to the ICU at seven urban hospital in Japan. The prevalence of VAEs, including its three subtypes, and in-ICU mortality were researched.

Results: Forty-nine VAEs were identified, affecting 5.7% of patients requiring MV for ≥ 2 days and 6.4 per 1,000 MV days. Mortality in those who developed VAEs was 42.9%, significantly higher than the rest of the cohort (*vs.* 15.4%, $P < 0.001$). The overall equivalent distribution of the three VAEs subtype incidences was evaluated: the incidences of VAC only, IVAC only and PVAP were 2.20, 1.90 and 2.29 per 1,000 MV days respectively ($P = 0.933$). However, VAE etiology and mortality was facility dependent. ICUs with a large proportion of surgical patients and more severe cases tended to have increased VAE incidence, with a converse decrease in closed ICUs.

Conclusions: The prevalence of VAEs appears low in Japanese ICUs. Nonetheless, mortality was substantially higher in patients who developed VAEs. Although some potential indices of VAEs are suggested to serve as QIs, additional studies to elaborate its practicality would further be required.

Introduction

In 2013, the Centers for Disease Control and Prevention (CDC)/the National Healthcare Safety Network (NHSN) issued new surveillance algorithms for ventilator-associated events (VAEs) (1). VAEs are comprehensive respiratory complications that occur in conjunction with use of mechanical ventilation (MV). The VAE definition was developed as a new indicator of quality of care in intensive care unit (ICU) to replace previously used ventilator-associated pneumonia (VAP) (2-4). Its advantages are all objective, simple, and potentially automatable. CDC/NHSN has placed emphasis on shifting surveillance away from traditional VAP to VAEs to eliminate subjectivity in surveillance (5-8). Because of promulgation of VAEs, a number of studies have been conducted in the United States and other Western countries (9-14) to evaluate its practicality as a quality indicator (QI) in ICU. The recent reports demonstrated that VAEs were associated with prolonged use of MV (11,15,16) prolonged ICU stay (2,12,17) and increased mortality (15,18,19).

However, information on VAEs in non-Western countries is scarce, with there being no literature on them, except for a few reports (19-21). The value of VAEs as QIs is uncertain. The extent to which VAEs affect patients is unknown. Evidence supporting its use by clinicians in non-Western countries is limited. VAEs should also be evaluated for its practicality as QIs and potential impact on future quality improvement outside Western countries. The first step in this effort is to clearly determine the incidence and mortality rate of VAEs.

The purpose of this preliminary study was to investigate the incidence and its associated factors, and mortality rate of VAEs in Japan.

Methods

The study was reviewed and approved by the Institutional Review Board (IRB) of the Mie University Graduate School of Medicine. The IRB approved an opt-out and waiver of consent for use in this project due to the low risk of injury, subject burden, and disclosure of personal information (IRB number: 1468). To research the prevalence of VAEs in Japanese ICUs we conducted a multi-center, retrospective review of patient medical records. We analyzed the medical records of patients who presented to seven affiliated ICUs (consisting of five universities and two community hospitals) between January 2014 and December 2014.

Definitions and measures

VAEs and ventilator-associated conditions (VACs) were defined as per CDC guidelines (1,5): the baseline period was defined as the two calendar days immediately preceding the first day of increased daily minimum (positive end-expiratory pressure) PEEP or (fraction of inspired oxygen) FiO_2 . A period of ventilator stability or improvement was defined as ≥ 2 calendar days of stable or decreased daily minimum FiO_2 or PEEP values. After a period of ventilator stability or improvement, a VAE was noted if the patient had at least one of the following indicators of worsening oxygenation: (I) an increase in the daily minimum FiO_2 of ≥ 0.2 over the daily minimum FiO_2 in the baseline period sustained for ≥ 2 calendar days and/or (II) an increase in the daily minimum PEEP values of ≥ 3 cmH_2O over the daily minimum PEEP in the baseline period sustained for ≥ 2 calendar days. Infection-related ventilator-associated complication (IVAC) was defined as the presence of VAC in a patient who also fulfilled the following criteria: ≥ 4 days of requiring one or more new antibiotics and any one of the following within 2 days before or after the day of VAC onset (excluding the first 2 days of MV): white blood cell count of $\leq 4,000$ or $\geq 12,000$ cells/mm^3 , temperature of < 36 or > 38 $^{\circ}\text{C}$. Possible and probable ventilator-associated pneumonia (PVAP) was defined as the presence of IVAC in a patient who also had evidence of pneumonia (e.g., positive culture of lower respiratory secretions, positive diagnostic test for selected respiratory viruses, and objectively defined purulent lower respiratory secretions).

Regarding the subtypes of VAEs, VAC only (same meaning as non-infectious complication) was defined as a patient meeting the VAC criteria not IVAC. Similarly, IVAC only (same meaning as infectious complications other than pneumonia) was defined as a patient meeting the IVAC criteria but not PVAP (15).

The incidence rate and distribution of VAEs and each subtype of VAEs were determined. Then, we investigated if VAEs were related to mortality. We identified the subtypes of VAEs associated with high mortality. Finally, we explored what type of facilities can have high incidence of VAE.

Statistics

Of the 4,541 patients admitted to the ICU during the study period, 1,464 patients (≥ 18 years of age) were mechanically ventilated. Of these, 785 patients received MV for ≥ 2 days were analyzed in this study (Figure 1). Continuous variables

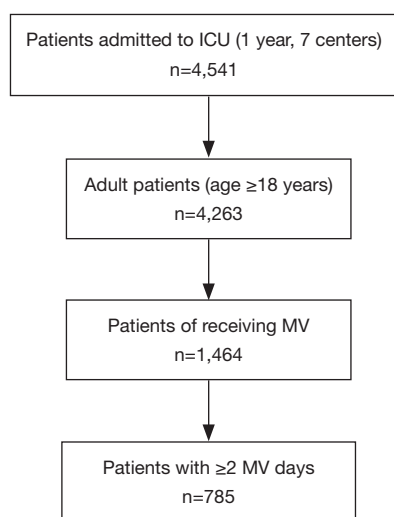

Figure 1 Schematic of the patient selection process.

were summarized using mean and standard deviation (SD). Categorical variables were numerically summarized and percentages presented where appropriate. The VAEs and No VAE groups were compared by the Student *t*-test for continuous variables and by chi-square test for categorical variables. One way ANOVA and chi-square test were used to compare the prevalence and mortality among VAE subtypes. The VAE incidence and mortality rate among the facilities were compared using chi-square test and multiple testing controlled by the Benjamini–Hochberg procedure (22). To determine the type(s) of facility with high VAE incidence, VAE prevalence was analyzed by the Generalized linear model (GLM) to test the impact of age distribution, overall ICU severity (APACHE II score), and unit type. The rationale for these thresholds of stratification are summarized as follows: (I) 65 years of age as the threshold: First, based on survey results of ICU functions in Japan, the average age of ICU patients was 66 years old (23). Second, pre-elderly is defined as 65 years old in Japan. Third, the median value of this study was 65 years. (II) APACHE II score of 20 as the threshold: An APACHE II score of 20 is generally observed as a dividing ridge as the predicted mortality rate is 20% and 40%, respectively, for a score of 20 or less and 20 or more, which is a large difference (24). (III) Surgical patient proportion: In a Japanese standard ICU, the percentage of surgical patient is about 45 (23). (IV) ICU type: previous studies have shown that the prognosis of ICU patients is better in closed ICU than in non-closed (open/semi-open) ICU (25). All patients in a closed-ICU are cared for by intensivist on duty at all times. The

adjusted odd ratio (OR) was calculated.

All statistical tests were two-sided, and significance was defined as $P < 0.05$. SAS software v9.3 for Windows (SAS Institute, Cary, North Carolina) was used for statistical analyses.

Results

The facilities had a combined total of 4,963 hospital beds (mean 709, SD 370), 120 of which were ICU beds (mean 17.1, SD 9.2). Of the 120 ICU beds, 70 were mixed general ICU, with the remaining beds classified as “other” types of ICU beds (including 10 medical, 12 surgical, and 28 emergency beds). Two of the ICUs were managed totally by intensivists (closed type ICU) and others were not.

Patients’ characteristics and backgrounds are summarized in *Table 1*. Mean APACHE II score was 23.5 (Max: 31; Min: 19). Overall, approximately half of the patients comprised non-surgical patients including out of hospital or inpatient emergency (47.5%) and the remaining were post-surgical patients (52.5%). Cardiovascular disease was the most frequent cause, accounting for 49.0%, followed by respiratory disease at 17.1%. Patient characteristics between the VAE and No VAE groups are as follows. Proportion of males was high in the VAEs group ($P = 0.043$), while mean age and average APACHE II score were not statistically significantly different. There was also no significant bias for diagnosis between the two groups.

VAEs incidence

VAEs incidence and characteristics are displayed in *Table 2*. We noted 49 total VAEs, which corresponded to 1.1% of total ICU patients and 5.7% of patients receiving ≥ 2 days of MV. The average incidence rate per facility was 7 cases per year. *Table 2* also displays the total number of VAC ($n = 49$), IVAC ($n = 29$), and PVAP ($n = 16$) cases. Converting these numbers to 1,000 MV days, the incidences were 6.40 (VAC), 4.19 (IVAC), and 2.29 (PVAP) cases per 1,000 MV days.

With regard to VAE subtypes, separate incidences were determined for VAC only (2.20), IVAC only (1.90), and PVAP (2.29) per 1,000 MV days and were not statistically different ($P = 0.933$). Of the 49 VAEs, 40.8% were VAC only, 26.5% were IVAC only, and 32.7% were PVAP ($P = 0.322$) (*Table 2*). In this study, non-pneumonia (VAC only + IVAC only) accounted for 67.3% of VAEs. Infectious complications (IVAC only + PVAP) were 59.2% of VAEs (*Table 2*).

Table 1 Characteristics of enrolled patients

Variable	Total (n=785)	VAEs (n=49)	No VAE (n=736)	P value
Age, years, mean (SD)	66.4 (3.6)	63.2 (8.6)	69.0 (7.0)	0.187
Female	264 (33.6)	10 (20.4)	254 (34.5)	0.043
APACHE II score, mean (SD)	23.5 (4.0)	22.9 (3.3)	23.2 (4.6)	0.906
Admission type				
Medical	373 (47.5)	21 (42.9)	352 (47.8)	0.556
Emergency surgery	192 (24.5)	16 (32.7)	176 (23.9)	0.172
Elective surgery	220 (28.0)	12 (24.5)	208 (28.3)	0.626
Diagnosis				
Cerebrovascular disease	92 (11.7)	8 (16.3)	84 (11.4)	0.355
Liver and/or renal disease	61 (7.8)	6 (12.2)	55 (7.5)	0.262
Cardiovascular disease	385 (49.0)	19 (38.8)	366 (49.7)	0.143
Respiratory disease	134 (17.1)	8 (16.3)	126 (17.1)	1.000
Others	128 (16.3)	8 (16.3)	120 (16.3)	1.000
Total duration of MV, d	7,158	1,211	5,947	–
Duration of MV, d, mean (SD)	9.5 (2.8)	22.4 (10.7)	8.7 (3.1)	0.007
ICU length of stay, d, mean (SD)	14.3 (4.3)	25.2 (13.7)	13.6 (4.4)	0.054
Hospital length of stay, d, mean (SD)	55.5 (17.6)	79.9 (28.7)	54.3 (18.2)	0.070
ICU mortality in patients with ≥ 2 MV days	134 (17.1)	21 (42.9)	113 (15.4)	<0.001

Data are presented as n (%), except where noted otherwise. SD, standard deviation; APACHE, Acute Physiology and Chronic Health Evaluation; MV, mechanical ventilation; ICU, intensive care unit.

Table 2 Ventilator-associated events incidence and mortality

VAEs	Total number	Mean (SD)	Incidence rate			Mortality, n (%)
			Per patients of receiving MV of ≥ 2 days (%), mean (SD)	Per 1,000 MV days, mean (SD)	Per VAEs (%)	
VAC	49	7.0 (6.1)	5.7 (2.8)	6.40 (3.2)	–	21 (42.9)
IVAC	29	4.1 (3.7)	3.3 (1.6)	4.19 (3.0)	–	12 (41.4)
PVAP	16	2.3 (2.9)	1.7 (1.8)	2.29 (2.4) [†]	32.7 [§]	5 (31.3) [¶]
VAC only	20	2.9 (3.0)	2.3 (2.3)	2.20 (2.0) [†]	40.8 [§]	9 (45.0) [¶]
IVAC only	13	1.9 (1.6)	1.6 (1.2)	1.90 (1.6) [†]	26.5 [§]	7 (53.8) [¶]

Data are presented as n or mean and SD, except where noted otherwise. [†], P=0.933; [§], P=0.322; [¶], P=0.459. SD, standard deviation; VAE, ventilator-associated event; VAC, ventilator-associated condition; IVAC, infection-related ventilator-associated complication; PVAP, possible and probable ventilator-associated pneumonia; MV, mechanical ventilation.

Figure 2 (left panel) shows VAE incidence across all seven facilities. All facilities had VAE with no statistically significant difference in VAE incidence (P=0.252). However, there was variation width in incidence rates. In addition,

the pathoetiology of VAEs were facility dependent. For example, pneumonia did not occur in facilities D, F, and G, only pneumonia occurred in facility A, noninfectious complications did not occur in facility C, and noninfectious

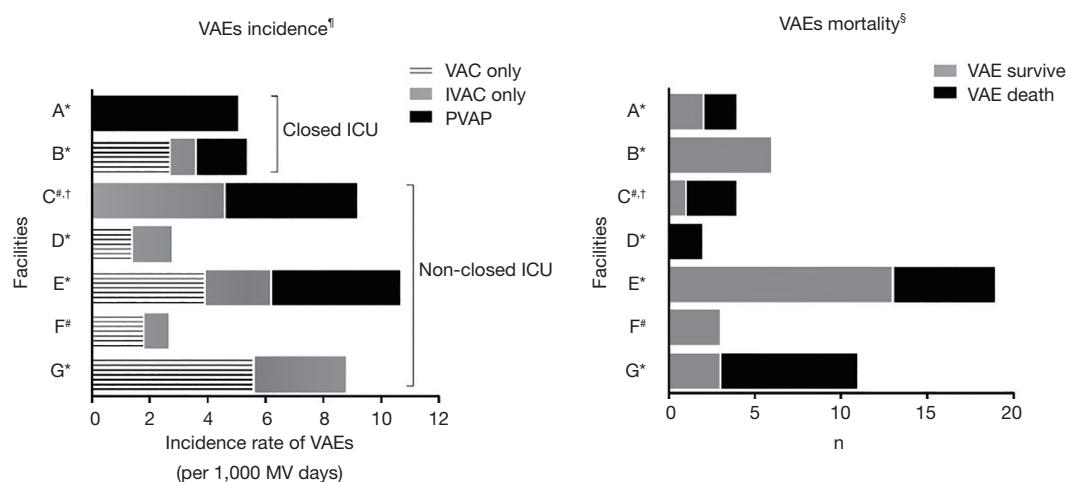

Figure 2 VAEs incidence and mortality in each facility. *, University hospital; #, Community hospital; †, Hospital with protocol driven mechanical ventilator settings; ¶, left panel shows that there was no statistically significant difference in the incidence of VAEs between 7 facilities ($P=0.252$), however, there was variation width in incidence rate; §, right panel shows that facility B had low VAE mortality, and facility G had high VAE mortality ($P<0.05$ from multiple testing controlled by the Benjamini-Hochberg procedure). VAE, ventilator-associated event; VAC, ventilator-associated condition; IVAC, infection-related ventilator-associated complication; PVAP, possible and probable ventilator-associated pneumonia.

Table 3 Generalized linear model (GLM) showing association of VAEs incidence with characteristics of the facilities

Risk variable	Adjusted β coefficient	SE	Z score	Adjusted odds ratio	P value
Closed ICU	-1.488	0.410	-3.632	0.23	<0.001
Mean age (≥ 65 years)	1.418	0.765	1.853	4.13	0.064
Mean APACHE II score (≥ 20)	1.904	0.927	2.054	6.71	0.040
Mean rate of surgical patient ($\geq 45\%$)	3.057	0.746	4.100	21.27	<0.001

VAE, ventilator-associated event; SE, standard error; APACHE, Acute Physiology and Chronic Health Evaluation; ICU, intensive care unit.

complications mainly occurred in facility G.

The adjusted odds ratios calculated by the generalized linear model (GLM) in order to investigate the relationship between facility features and prevalence of VAEs were as follows: 0.23 for “closed-ICU”; 6.71 for “APACHE II score 20 or more”; and 21.27 for “the ratio of surgical cases to 45% or more”. There was statistical significant difference in each of these factors (Table 3). Incidence of VAEs in ICU was found to increase with a large proportion of surgical patients and more severe patients, while converse decreased in closed ICU.

VAEs outcomes

Death was observed in 134 (17.1%) of the ICU 785 patients with ≥ 2 MV days (Table 1). Of these patients, 21 (15.7%)

had VAEs. This reflected a rate of about 3.0% of patients with ≥ 2 MV days and 0.5% of total ICU patients. When analyzing the relationship between the number of deaths and development of VAEs, the mortality rate of the VAEs group was 42.9% (21/49). This was significantly different from mortality rates observed in the No VAE group (15.4%: 113/736; $P<0.001$, Table 1). The (non-adjusted) odds ratio for death in the VAE group was 4.13 times that of the No VAE group. Number needed to harm (NNH) was 3.6. There were no differences in ICU mortality among the three subtypes ($P=0.459$, Table 2), with all three groups showing a tendency toward high mortality. The mean duration of MV was statistically significantly longer for the VAE group than for the No VAE group (22.4 vs. 8.7, $P=0.007$), and the average length of ICU stay also tended to be longer for the VAE group (25.2 vs. 13.6, $P=0.054$).

Figure 2 (right panel) shows VAE mortality across all seven facilities. Variation width among facilities in VAE mortality was observed. For example, facility B had no VAE death, while facility G had high VAE mortality rate ($P < 0.05$).

Discussion

This preliminary research established the prevalence of VAEs (5.7% of patients with ≥ 2 MV days, 6.40/1,000 MV days) in Japanese ICU. The presence of VAEs, specifically VAC or IVAC, was related to mortality. We observed the variety of incidence rate, VAE mortality, and its etiology among the centers.

Overall, the low incidence of VAEs in this study is striking. Data from a Canadian study of patients in ICUs with APACHE II scores of 21–23 found an incidence of 11% for patients with ≥ 2 MV days (17). Zhu *et al.* reported VAEs in 15% of patients with ≥ 2 MV days and overall incidence was 11.1/1,000 MV days (19). According to a report by Hayashi *et al.* conducted in a single center with APACHE II scores of 21–22, VAEs were found in 28% of the patients with ≥ 2 MV days (11). Compared to these reports with similar APACHE II scores as our study, we found that our VAE incidence was low.

The mortality rate in VAE patients is about 43%, which was not markedly different from that reported in previous investigations, in which the mortality rates were 11% (11), 25% (17), and 47% (19). In addition, there were statistically significant differences in the mortality rates relative to the presence or absence of VAEs, which was similar to previous results (2,12,15,19,20). As important outcomes such as mortality, duration of MV, and length of ICU stay were significantly different between the VAE and No VAE groups, VAEs may have negative consequences for MV patients. Our study results are based on statistical analysis without controlling for confounding factors, but our cohort has the same background factors such as age, admission type, disease classification, and severity. Thus these results suggest that VAEs may adversely affect MV patients.

In this study, we found that incidence and distribution of VAE subtypes, etiology and mortality were different in each facility. This is important for considering a future VAEs prevention program. There is a potential for variation in the major risks of VAEs among the facilities, depending on the etiological components of clinical VAEs in each ICU. The response to preventive VAE interventions [ex. sedative agents (26), tapered-cuff tracheal tube (27), ventilator bundle (28)] varies depending on the dominant

pathoetiological VAE (29). The diverse pathoetiological VAE conditions suggests that directly applying the traditional VAP bundle (30) may not be appropriate when addressing a quality improvement initiative for VAE prevention, most notably for facility D, F, and G. Thus, development of preventive VAE measures should be based on the VAE pathoetiology in each ICU.

Japanese ICUs with a large proportion of surgical patients and more severe cases tended to have increased VAE incidence, with a converse decrease in closed ICUs. This is important when implementing VAEs surveillance as a public reporting system in Japan. Our findings indicated that it is necessary to stratify the data in order to compare incidence rate across multiple centers. Based our results, the following stratification method is suggested for Japan: (I) to categorize facilities based on an average APACHE II score that is greater than 20 or less than 20; (II) to categorize by Closed/Non-closed ICU; (III) and to categorize by surgical/medical ICU. Unlike the United States, functional differentiation of ICU has not progressed in Japan, and stratification by APACHE II score is therefore considered suitable.

Overall, there were no differences in the mortality rates among VAC only, IVAC only, and PVAP as VAE subtype, which is in line with results from Klompas *et al.* in USA (15). The globally equivalent distribution of the incidence of the three subtypes in this study differs from that in reports of prior studies, where high rates (50–63%) were observed for VAC only as non-infectious complications (8,12,15–20). The reason for this disparity is unknown; however, the rate of complications of non-pneumonia was 67.3% of all VAEs in our study, which is in line with rates reported in previous studies (8,12,15,18–20). Our study suggests that targeting pneumonia as an isolated ICU QI is inadequate. The monitoring of “non-infectious complications” and “infectious complications other than pneumonia” may also be important. These findings support shifting the focus away from pneumonia only in initiatives of CDC/NHSN. Our data suggests the importance of surveillance not only pneumonia of but also non-infectious and non-pneumonia factors, broader classification of respiratory deterioration, as a significant associated factor for poor outcome.

It remains uncertain that VAEs could become a potential ICU QI. The prevalence of VAEs is approximately 1.0% of the total ICU patients in this study, indicating its limited use for QI. It is also important to consider the extent to which QIs contribute to improving outcomes. One study indicates that preventable VAEs comprised only 37% of the total VAEs (18). If we apply this conclusion to our data,

preventative efforts may potentially reduce the observed VAEs from 49 to 31 of 4,541 total ICU patients and VAE-associated deaths from 21 to 13 (decrease rate: 1.8 per 1,000 ICU patients and 1.0 per 100 patients with ≥ 2 MV days), an extremely small impact on QI for the overall ICU population (31).

Study limitations

Because we did not collect detailed patient-specific information, a more elaborate methodology is required to correctly evaluate if VAEs could be a modifiable outcome or just a surrogate of disease severity.

Conclusions

This study has highlighted some potential of VAEs as a new QI and the challenges facing Japanese ICUs in its use. VAEs may affect ICU mortality rates, however, uncertainty about the extent of the true impact on patients' outcome and a deficit of robust preventive approaches for VAEs would discourage VAE as a QI measure. Although some potential indices of VAEs are suggested to serve as QIs, additional studies to elaborate its practicality or adequacy would further be required.
